Abstract

The Heavy Photon Search (HPS), an experiment to search for a hidden sector photon in fixed target electroproduction, is preparing for installation at the Thomas Jefferson National Accelerator Facility (JLab) in the Fall of 2014. As the first stage of this project, the HPS Test Run apparatus was constructed and operated in 2012 to demonstrate the experiment's technical feasibility and to confirm that the trigger rates and occupancies are as expected. This paper describes the HPS Test Run apparatus and readout electronics and its performance. In this setting, a heavy photon can be identified as a narrow peak in the e^+e^- invariant mass spectrum, above the trident background or as a narrow invariant mass peak with a decay vertex displaced from the production target, so charged particle tracking and vertexing are needed for its detection. In the HPS Test Run, charged particles are measured with a compact forward silicon microstrip tracker inside a dipole magnet. Electromagnetic showers are detected in a PbWO₄ crystal calorimeter situated behind the magnet, and are used to trigger the experiment and identify electrons and positrons. Both detectors are placed close to the beam line and split top-bottom. This arrangement provides sensitivity to low-mass heavy photons, allows clear passage of the unscattered beam, and avoids the spray of degraded electrons coming from the target. The discrimination between prompt and displaced e^+e^- pairs requires the first layer of silicon sensors be placed only 10 cm downstream of the target. The expected signal is small, and the trident background huge, so the experiment requires very large statistics. Accordingly, the HPS Test Run utilizes high-rate readout and data acquisition electronics and a fast trigger to exploit the essentially 100% duty cycle of the CEBAF accelerator at JLab.

Keywords: silicon, microstrip, tracking, vertexing, heavy photon, dark photon, electromagnetic calorimeter

1 **1. Introduction**

2 The heavy photon (A'), aka a “hidden sector” or
3 “dark” photon, is a massive gauge boson which couples
4 weakly to electric charge by mixing with the Standard
5 Model photon [1, 2]. Consequently, it can be radiated
6 by electrons and subsequently decay into e^+e^- pairs, al-
7 beit at rates far below those of QED trident processes.
8 Heavy photons have been suggested by numerous be-
9 yond Standard Model theories [3] to explain the discrep-
10 ancy between theory and experiment of the muon’s $g-2$
11 [4], and as a possible explanation of recent astrophysical
12 anomalies, e.g. [5, 6, 7]. Heavy photons couple directly
13 to hidden sector particles with “dark” or “hidden sec-
14 tor” charge; these particles could constitute all or some
15 of the dark matter, e.g. [8, 9]. Current phenomenology
16 highlights the $20 - 1000 \text{ MeV}/c^2$ mass range, and sug-
17 gests that the coupling to electric charge, ϵe , has ϵ in the
18 range of $10^{-3} - 10^{-5}$. This range of parameters makes
19 A' searches viable in medium energy fixed target elec-
20 troproduction [10], but requires large data sets and good
21 mass resolution to identify a small mass peak above the
22 copious QED background. At small couplings, the A'
23 becomes long-lived, so detection of a displaced decay
24 vertex can reject the prompt QED background and boost
25 experimental sensitivity.

26 The HPS experiment [11] is preparing for installation
27 in Hall-B at JLab in the Fall of 2014 and searches for
28 electro-produced A' when 2.2-6.6 GeV electrons from
29 the JLab CEBAF accelerator interact with Tungsten nu-
30 clei in a thin (0.25% R.L.) target foil. The HPS experi-
31 ment uses both invariant mass and secondary vertex sig-
32 natures to search for A' decays into e^+e^- pairs. At CE-
33 BAF energies, the A' decay products are boosted along
34 the beam axis with small opening angles. For couplings
35 $\epsilon << 10^{-3}$, A' decay lengths range from millimeters to
36 tens of centimeters and beyond. Accordingly the track-
37 ing detectors cover opening angles down to 15 mrad and
38 are placed just 10 cm downstream of the target.

39 HPS employs a 90 cm long silicon tracking and
40 vertexing detector located inside a dipole magnet to
41 measure momenta and decay vertex positions. A fast
42 PbWO₄ electromagnetic calorimeter downstream of the
43 magnet provides the trigger and electron identification.
44 Both the silicon tracker and the ECal have \sim ns tim-
45 ing resolution, which eliminates much of the out-of-
46 time background from multiple scattered beam elec-
47 trons. Fast front end electronics and high trigger and

48 data rate capability and the effectively 100% duty cycle
49 of the CEBAF accelerator allow HPS to accumulate the
50 very large statistics needed to be sensitive to the highly
51 suppressed production of heavy photons.

52 The HPS Test Run, using a simplified version of the
53 HPS apparatus, was proposed and approved at JLab as
54 the first stage of HPS. Its purposes included demonstra-
55 ting that the apparatus and data acquisition systems are
56 technically feasible and the trigger rates and occupan-
57 cies to be encountered in electron-beam running are as
58 simulated. Given dedicated running time with electron
59 beams, the HPS Test Run apparatus is capable of search-
60 ing for heavy photons in unexplored regions of param-
61 eter space. Therefore, key design criteria and require-
62 ments for HPS and the HPS Test Run apparatus are the
63 same:

- 64 • uniform acceptance between 15 and approximately
65 70 mrad in the forward region to catch boosted de-
66 cay products close to the beam,
- 67 • beam passage through the apparatus in vacuum, to
68 eliminate direct interactions with the detector and
69 minimize beam gas interactions,
- 70 • detector components that can survive and effi-
71 ciently operate in a high radiation environment
72 with some localized doses at the 100 Mrad level,
- 73 • high-rate electronics, handling trigger rates up to
74 50 kHz and data rates of 100 MB/s to permanent
75 storage,
- 76 • a flexible, redundant and efficient trigger for select-
77 ing electron and positron pairs, capable of handling
78 rates up to 50 kHz,
- 79 • hit reconstruction efficiency higher than 99% and
80 average track reconstruction efficiency higher than
81 98% for electrons and positrons,
- 82 • 2 ns hit time resolution in the silicon vertex tracker,
- 83 • A' mass resolution of 2.5% or better, which trans-
84 lates to momentum resolution of 4.5% and angular
85 resolution 2 mrad/ $p(\text{GeV}/c)$ for $B=0.5 \text{ T}$,
- 86 • resolution of distance of closest approach to the
87 beam axis less than 250 (100) μm for tracks with
88 0.5 (1.7) GeV/c . This gives a decay length resolu-
89 tion of about 1 mm for a 100 $\text{MeV}/c^2 A'$.
- 90 • PbWO₄ electromagnetic calorimeter energy res-
91 olution $\Delta E/E \leq 5\%/\sqrt{E}$ and transverse segmenta-
92 tion $\sim 1.5 \text{ cm}$ (Moliere radius in PbWO₄). The

93 energy resolution for triggering is less stringent ($\Delta E/E \leq 10\%/\sqrt{E}$) because the electrons and
94 positrons of interest are relatively hard. The good
95 segmentation provides good spatial resolution and
96 guarantees minimal shower overlap with back-
97 ground hits.
98

99 The HPS Test Run apparatus was installed on April
100 19, 2012, and ran parasitically in the photon beam of
101 the HDice experiment [12] until May 18. The JLab run
102 schedule precluded any dedicated electron beam run-
103 ning, but the HPS Test Run was allowed an 8h dedicated
104 photon beam run at the end of scheduled CEBAF run-
105 ning. During this dedicated period, e^+e^- pairs, produced
106 in a gold foil upstream of the experiment, were stud-
107 ied. With no dedicated electron beam running, it was
108 not possible to search for an A' . However, the final run-
109 ning provided enough data to demonstrate the function-
110 ality of the apparatus, document its performance, and
111 explore trigger rates, as shown below.

112 This paper reviews the HPS Test Run apparatus, doc-
113umenting the performance of the trigger, data acquisi-
114tion, silicon tracking and vertex detector, and the elec-
115tromagnetic calorimeter at, or close to, the level re-
116quired for the HPS experiment.

117 2. Detector Overview

118 The HPS Test Run apparatus was designed to run
119 in Hall B at JLab using the CEBAF 499MHz electron
120 beam at energies between 2.2 and 6.6 GeV and cur-
121 rents between 200 and 600 nA. The overall design of
122 the experiment follows from the kinematics of A' pro-
123duction which typically results in a final state particle
124 within a few degrees of the incoming beam, especially
125 at low $m_{A'}$. Detectors must therefore be placed close
126 to the beam. The intense electron beam enlarges down-
127 stream after multiple scattering in the target and elec-
128 trons which have radiated in the target disperse horizon-
129 tally in the field of the analyzing magnet. Together they
130 constitute a “wall of flame” which must be completely
131 avoided. Accordingly, the apparatus is split vertically
132 to avoid a “dead zone”, the region within ± 15 mrad of
133 the beam plane. In addition, the beam is transported in
134 vacuum through the tracker to minimize beam-gas inter-
135 action backgrounds. Even with these precautions, the
136 occupancies of sensors near the beam plane are high,
137 dominated by the multiple Coulomb scattering of the
138 primary beam, so high-rate detectors, a fast trigger, and
139 excellent time tagging are required to minimize their
140 impact. The trigger comes from a highly-segmented

141 lead-tungstate ($PbWO_4$) crystal calorimeter located just
142 downstream of the dipole magnet.
143

144 A rendering of the apparatus installed on the beam line
145 is shown in Figure 1 and an overview of the coverage,
146 segmentation and performance is given in Table 1.

147 The silicon tracking and vertexing detector for the
148 HPS Test Run, or SVT, resides in a vacuum cham-
149 ber inside the Pair Spectrometer (PS) dipole magnet in
150 Hall B at JLab. The magnetic field strength was 0.5 T
151 oriented vertically throughout the run. The SVT has
152 five measurement stations, or “layers,” beginning 10 cm
153 downstream of the target. Each layer comprises a pair
154 of closely-spaced silicon microstrip sensors respon-
155 sible for measuring a single coordinate, or “view”. In-
156 troduction of a small (50 or 100 mrad) stereo angle
157 between the two sensors of each layer provides three-
158 dimensional tracking and vertexing throughout the ac-
159 ceptance of the detector. In order to accommodate the
160 dead zone, the SVT is built in two halves that are ap-
161 proximately mirror reflections of one another about the
162 plane of the nominal electron beam. Each layer in one
163 half is supported on a common support plate with inde-
164 pendent cooling and readout.

165 The electromagnetic calorimeter (ECal) is also split
166 into two halves. Each half of the ECal consists of
167 221 $PbWO_4$ crystals arranged in rectangular formation.
168 There are five rows with 46 modules in each row except
169 the row closest to the beam plane which has 37. The
170 light from each crystal is read out by an Avalanche Photo-
171 diode (APD) glued on the back surface of the crys-
172 tal. Signals from the APDs are amplified using custom-
173 made amplifier boards before being sent to the data ac-
174 quisition electronics.

175 The Data Acquisition system combines two architec-
176 tures, the Advanced Telecom Communications Archi-
177 tecture (ATCA) based SVT readout system and VME-
178 bus Switched Serial (VXS) based digitization and trig-
179 gering system for the ECal.

180 3. The HPS Test Run Beamline

181 Since an electron beam was unavailable, the HPS Test
182 Run detected the electrons and positrons produced by
183 interactions of the secondary photon beam with a thin
184 foil just upstream of the detectors. The HPS Test Run
185 studied the performance of the detectors and the mul-
186 tiple coulomb scattering of the electrons and positrons.
187 Figure 2 shows the layout of the setup on the beam line.
188 The SVT was installed inside the Hall B pair spectrom-
189 eter magnet vacuum chamber with the ECal mounted

Figure 1: Rendering of the HPS Test Run apparatus installed on the beam line.

Table 1: Overview of the coverage, segmentation and performance of the HPS Test Run detector. The σ_{d_0} is the track impact parameter resolution of the SVT at the nominal electron target position. σ_{pos} is the estimated position resolution perpendicular to the strip direction on the silicon sensors of the SVT.

System	Coverage (mrad)	# channels	ADC (bit)	# layers	Segmentation	Time resolution (ns)	Performance
SVT	$15 < \theta_y < 70$ (5 hits)	12780	14	5 (stereo layers)	$30 \mu\text{m}$ (sense) $60 \mu\text{m}$ (readout) ($\sigma_{pos} \approx 6 \mu\text{m}$)	2.5	$\sigma_{d0,y} \approx 100 \mu\text{m}$ $\sigma_{d0,x} \approx 300 \mu\text{m}$ $\sigma_{d0,z} \approx 1 \text{ mm}$
ECal	$15 < \theta_y < 60$	442	12	1	$1.33 \times 1.33 \text{ cm}^2$ $1.6 \times 1.6 \text{ cm}^2$	4 (trigger)	$\sigma(E)/E \approx 4.5\%/\sqrt{E}$ Ref. [13, 14, 15]

Figure 2: Layout of the HPS parasitic run.

downstream of it. Both the SVT and the ECal were retracted off the beam plane compared to nominal electron beam running to allow clean passage of the photon beam through the system.

The photon beam was generated in the interaction of 5.5 GeV electrons with a $10^{-4} X_0$ gold radiator located ≈ 9 m upstream of the PS. The primary beam and scattered electrons are deflected away from detectors by the dipole magnet of the photon tagging system. During the dedicated HPS Test Run period, the collimated (6.4 mm diameter) photon beam passes through the PS pair converter gold foil and later the HPS system. The PS pair converter was located ≈ 77 cm upstream of the first layer of the SVT.

Data was taken on three different converter thicknesses with photon fluxes between 0.4 and $1.3 \times 10^8/\text{s}$ at photon energies between 0.55 and 5.5 GeV produced by a 30 to 90 nA electron beam. Data was measured for both polarities of the PS dipole magnet. The photon beam line during the HPS Test Run produced a relatively large number of e^+e^- pairs originating upstream

Converter thickn. (% X_0)	Duration (s)	e^- on radiator (μC)
0	1279	88.1
0.18	2640	193.5
0.45	2149	140.7
1.6	911	24.4

Table 2: Measured integrated currents for the dedicated photon runs.

of the converter position. This contribution was measured during data taking with “empty” converter runs, i.e. removing the converter but with all other conditions the same. The runs taken during the time dedicated to HPS Test Run are summarized in Table 2.

4. Silicon Vertex Tracker

The Silicon Vertex Tracker (SVT) enables efficient reconstruction of charged particles and precise determination of their trajectories. This allows A' decays to be distinguished from background via simultaneous measurements of the invariant mass of e^+e^- decay products and the position of decay vertices downstream of the target.

The design of the SVT is primarily driven by physics requirements and constraints from the environment at the interaction region. The A' decay products have momenta in the range of 0.4-2.0 GeV/c (from a 2.2 GeV beam), so multiple scattering dominates mass and vertexing uncertainties for any possible material budget. The SVT must therefore minimize the amount of material in the tracking volume. The signal yield for long-lived A' is very small, so the rejection of prompt vertices must be exceedingly pure, on the order of 10^{-7} , in order to eliminate all prompt backgrounds. To achieve the required vertexing performance the first layer of the SVT must be placed no more than about 10 cm downstream of the target. At that distance, it is found that the active region of a sensor can be placed as close as 1.5 mm from the center of the beam, defining the 15 mrad “dead zone” mentioned previously, to maximize low-mass A' acceptance with decay products nearly collinear with the beam axis. At the edge of this “dead zone”, the radiation dose approaches 10^{15} electrons/cm 2 /month, or roughly 3×10^{14} 1 MeV neutron equivalent/cm 2 /month [16], requiring the sensors to be actively cooled. Meanwhile, very low-energy delta rays from beam-gas interactions would multiply the density of background hits, so the SVT must operate inside the beam vacuum. Finally, in order to protect the sensors, the detector must be movable

so that it can be retracted during periods of uncertain beam conditions or beam tuning.

Good mass resolution is needed across the interesting mass range to discover the A' signal on top of the copious QED background in the bump-hunt search. Track momentum and angular resolution of 4-5% and 1-4 mrad (across the momentum range in the non-bend plane which dominates the measurement), respectively, translates into a 2.5% mass resolution for A' decay opening angles between 15-70 mrad [11]. With multiple scattering dominating both mass and vertexing uncertainties, spatial hit resolution less than 50 μm are required in the non-bend plane in the first few layers which dominates the vertexing performance and about twice that in the non-bend plane.

High background occupancies, up to 4 MHz/mm 2 locally, in the region closest to the beam result from beam electrons undergoing multiple scattering in the target. These background hits are rejected by requiring the time reconstruction of each hit to be better than 2 ns.

4.1. Layout

The layout of the SVT is summarized in Table 3 and rendered in Figure 3. Each of the layers is comprised of a pair of closely-spaced silicon microstrip sensors mounted back-to-back to form a module. A 100 mrad stereo angle is used in the first three layers to provide higher-resolution 3D space points for vertexing. Using 50 mrad in the last two layers breaks the tracking degeneracy of having five identical layers and minimizes fakes from ghost hits to improve pattern recognition. Altogether, the SVT has 20 sensors for a total of 12780 readout channels.

Layer	1	2	3	4	5
z from target (cm)	10	20	30	50	70
Stereo angle (mrad)	100	100	100	50	50
Bend res. (μm)	≈ 60	≈ 60	≈ 60	≈ 120	≈ 120
Non-bend res. (μm)	≈ 6	≈ 6	≈ 6	≈ 6	≈ 6
# of sensors	4	4	4	4	4
Dead zone (mm)	± 1.5	± 3.0	± 4.5	± 7.5	± 10.5
Power cons. (W)	6.9	6.9	6.9	6.9	6.9

Table 3: Layout of the SVT.

The SVT is built in two separate halves that are mirror reflections of one another about the plane of the nominal electron beam. Each half consists of five modules mounted on a support plate that provides services to the

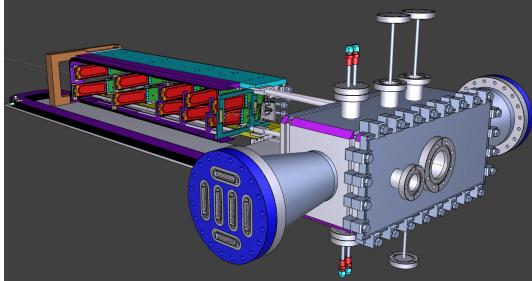

Figure 3: A rendering of the SVT showing the modules on their support plates held by the hinged C-support on the left and the motion levers on the right. The sensors are shown in red and the hybrid readout boards in green. The beam enters from the right through a vacuum box with flanges for services.

modules and allows them to be moved as a group relative to the dead zone. The two halves of the tracker are connected to hinges mounted on a C-shaped support just beyond the last layer that defines the nominal spacing between the upper and lower halves of the tracker. A shaft attached to each support plate in front of layer one extends upstream and connects to a linear shift that transfers motion into the vacuum box through bellows to open and close the two halves around the dead zone. The C-support is mounted to an aluminum baseplate that defines the position of the SVT with respect to the vacuum chamber. Figure 4 shows a photograph of both completed detector halves prior to final assembly.

Figure 4: Both halves of the HPS Test Run SVT after final assembly at SLAC. The cooling manifolds and integrated cable runs are clearly seen.

301

302 4.2. Components

303 The sensors for the SVT are $p+$ -on- n , single-sided, 304 AC-coupled, polysilicon-biased microstrip sensors fab- 305 ricated on $<100>$ silicon and have 30 (60) μm sense 306

(readout) pitch over their $4 \times 10 \text{ cm}^2$ surface. This 307 sensor technology was selected to match the require- 308 ment of $< 1\% X_0$ per layer, single-hit resolution bet- 309 ter than 50 μm and tolerance of a radiation dose of ap- 310 proximately 1.5×10^{14} 1 MeV neutron equivalent/ cm^2 311 for a six month run. The sensors, produced by Ham- 312 a-matsu Photonics Corporation, were originally meant 313 for the cancelled Run 2b upgrade of the DØ exper- 314 iment [17] which satisfied the requirement that the 315 technology must be mature and available within the time and 316 budget constraints.

317 Despite having only small spots with very high occu- 318 pancy (up to 4 MHz/mm^2) closest to the primary beam, 319 the rates are still high and lowering the peak occupancy 320 to approximately 1% for tracking requires a trigger win- 321 dows and hit time tagging of roughly 8 ns. The ECal 322 readout and trigger described in Sec. 5.3 can achieve 323 such resolution. To reach this performance the sen- 324 sors for the SVT are readout by the APV25 ASIC de- 325 veloped for the CMS experiment at CERN [18]. The 326 APV25 can capture successive samples of the shaper 327 output in groups of three at a sampling rate of approx- 328 imately 40 MHz. By fitting the known $CR-RC$ shaping 329 curve to these samples, the initial time of the hit can 330 be determined to a precision of 2 ns for $S/N \approx 25$ [19]. 331 For electron beam running, six-sample readout and the 332 shortest possible shaping time (35 ns) is used to best 333 distinguish hits that overlap in time. The APV25 ASICs 334 are hosted on simple FR4 hybrid readout boards, out- 335 side the tracking volume, with a short twisted-pair pig- 336 tail cable to provide power and configuration and signal 337 readout. Along with a single sensor, these are glued 338 to a polyimide-laminated carbon fiber composite back- 339 ing making up a half-module. A window is machined 340 in the carbon fiber leaving only a frame around the pe- 341 riphery of the silicon to minimize material. A 50 μm 342 sheet of polyamide is laminated to the surface of the 343 carbon fiber with 1 mm overhang at all openings to en- 344 sure good isolation between the back side of the sensor, 345 carrying high-voltage bias, and the carbon fiber which 346 is held near ground.

347 The sensor modules for the SVT consist of a pair 348 of identical half-modules, sandwiched back-to-back 349 around an aluminum cooling block at one end and a sim- 350 ilar PEEK spacer block at the other. Figure 5 shows a 351 single module after assembly. The cooling block pro- 352 vides the primary mechanical support for the module as 353 well as cooling via copper tubes pressed into grooves 354 in the plates. The spacer block defines the spacing be- 355 tween the sensors at the far end of the module, stiffens 356 the module structure, and improves the stability of the 357 sensor alignment. The average support material in the

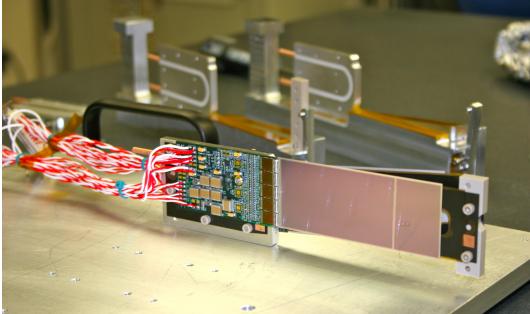

Figure 5: A prototype module assembly (foreground) with the 50 mrad (left) and 100 mrad (right) module assembly fixtures in the background. A pair of cooling blocks and a spacer block can be seen on the fixtures.

tracking volume is approximately 0.06% X_0 per double-sided module for a total material budget of 0.7% per layer.

The total SVT power consumption budget of about 50 W is removed by a water/glycol mixture circulated through a flexible manifold attached to the copper tubes in the cooling blocks. During the HPS Test Run the sensors were operated at around 23° C. The power consumption is dominated by five APV25 ASICs on each hybrid board consuming approximately 2 W, radiant heat load is less than 0.5 W per sensor and leakage current is only significant in a small spot after irradiation.

4.3. Production, Assembly and Shipping

Hybrids with APV25 ASICs underwent quick qualification testing and each half-module was run at low temperature ($\approx 5^\circ \text{C}$) and fully characterized for pedestals, gains, noise and time response after assembly. Of 29 half-modules built, 28 passed qualification testing, leaving eight spare modules after completion of the SVT. Only sensors capable of 1000 V bias voltage without breakdown were used. Full-module assembly and mechanical surveys were performed at SLAC before final assembly, testing and shipping of the SVT to JLab. A custom shipping container with nested crates and redundant isolation for shock and vibration was built in order to safely send the partly assembled SVT to JLab. At JLab, the entire SVT was integrated with the full DAQ and the power supplies before moving the module-loaded support plates to Hall B for final mechanical assembly and installation inside of the vacuum chamber.

4.4. Alignment

The SVT was aligned using a combination of optical, laser and touch probe surveys at SLAC and JLab. The

optical survey of individual modules with a precision of a few μm was combined with a touch-probe survey of the overall SVT support structure, with 25-100 μm precision, to locate the silicon sensor layers with respect to the support plates and the mechanical survey balls on the base plate. After full assembly and installation of the SVT at JLab, a mechanical survey of the SVT base plate position inside the pair spectrometer vacuum chamber is used to determine the global position of the SVT with respect to the CEBAF beam line. The resulting survey-based alignment has the position of the silicon sensors correct to within a few hundred microns measured from tracks in the HPS Test Run data. A more sophisticated global track-based alignment technique to reach final alignment precision well below 50 μm is being developed.

5. Electromagnetic Calorimeter

The electromagnetic calorimeter (ECal), installed downstream of the PS dipole magnet, performs two essential functions for the experiment: it provides a trigger signal to select what events to read out from the detector sub-systems and is used in the analysis to identify electrons and positrons. The technology and design choices are largely driven by the need for a compact forward design covering the SVT A' acceptance and able to fully absorb electrons and positrons with energy between 0.5-6.5 GeV. It needs granularity and signal readout speed to handle 1 MHz/cm² of electromagnetic background and to be radiation hard. While the trigger for A' events is largely insensitive to the energy resolution, in order to have the possibility to improve the energy resolution from the SVT measurement $\sigma(E)/E < 4.5\%/\sqrt{E}$ is needed.

The PbWO₄ crystal inner calorimeter of the CLAS detector [13, 14, 15], in operation since 2005 in Hall B, meets all the requirements set by HPS. The modules from this calorimeter have been subsequently repurposed for HPS.

5.1. Components

The ECal module shown in Figure 6 is based on a tapered 160 mm long PbWO₄ crystal with a 13.3 × 13.3 mm² (16 × 16 mm²) front (rear) face wrapped in VM2000 multilayer polymer mirror film. The scintillation light yield, approximately 120 photons/MeV, is read out by a 5×5 mm² Hamamatsu S8664-55 Avalanche Photodiode (APD) with 75% quantum efficiency glued to the rear face surface using MeltMount 1.7 thermal plastic adhesive. This results in about 8

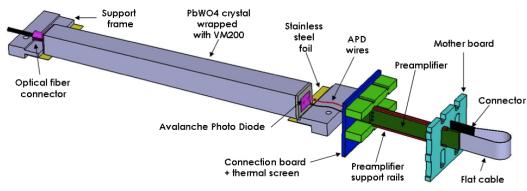

Figure 6: A schematic view of an ECal module.

Figure 7: Rendered layout view of the ECal looking downstream.

439 photoelectrons/MeV which needs to be amplified before
 440 fed into the FADC for digitization and processing. The
 441 maximum energy deposited in a crystal is expected to
 442 be 4.2 GeV which needs to match the input range of the
 443 FADC. The relatively low gain of the APD (~ 200) was
 444 compensated with custom-made preamplifier boards,
 445 that provide further amplification to match the 2 V dy-
 446 namic range of the FADC. With a total noise level of
 447 about 10 MeV and a resolution of about 1 ADC/MeV
 448 the ADC resolution fulfills the requirements from HPS.

449 5.2. Layout

450 Similar to the SVT, the ECal is built in two separate
 451 halves that are mirror reflections of one another about
 452 the plane of the nominal electron beam to avoid inter-
 453 ferring with the 15 mrad “dead zone”. As shown in Fig-
 454 ure 7, the 221 modules in each half, supported by alu-
 455 minum support frames, are arranged in rectangular for-
 456 mation with five layers and 46 crystals/layer except for
 457 the layer closest to the beam where nine modules were
 458 removed to allow a larger opening for the outgoing elec-
 459 tron and photon beams. Each half was enclosed in a
 460 temperature controlled box ($< 1^\circ \text{F}$ stability and $< 4^\circ \text{F}$
 461 uniformity) to stabilize the crystal light yield and the op-
 462 eration of the APDs and its preamplifiers. Four printed
 463 circuit boards mounted on the backplane penetrated the
 464 enclosure and were used to supply the ± 5 V operating
 465 voltage for the preamplifiers, 400 V bias voltage to the
 466 APDs, and to read out signals from the APDs. Each half
 467 of the ECal was divided into 12 bias voltage groups with
 468 a gain uniformity of about 20%.

469 During the HPS Test Run, both halves were held in
 470 place by four vertical bars attached to a rail above, plac-
 471 ing the front face of the crystals 147 cm from the up-
 472 stream edge of the magnet, with a 8.7 cm gap between
 473 the innermost edge of the crystals in the two halves.

474 5.3. Signal readout

475 After a 2:1 signal splitter, 1/3 of an amplified APD
 476 signal was fed to a single channel of a JLab flash ADC
 477 (FADC) board [20]. 2/3 of the signal was sent to a

478 discriminator module and then to a TDC for a timing
 479 measurement. The FADC boards are high speed VXS
 480 modules digitizing up to 16 APD signals at 250 MHz
 481 and storing samples in $8 \mu\text{s}$ deep pipelines with 12-bit
 482 resolution. When a trigger is received, the part of the
 483 pipeline from 5 samples before and 30 after the signal
 484 which crossed a programmable threshold (for the HPS
 485 Test Run this was set to ≈ 70 MeV) are summed and
 486 stored in a 17-bit register for readout. In addition a
 487 4 ns resolution timestamp of the threshold crossing is
 488 reported in the readout for each pulse. This scheme
 489 significantly compresses the data output of the FADC.
 490 During offline data analysis, a calibrated pedestal value
 491 is subtracted to obtain the actual summed energy. Two
 492 20-slot VXS crates with 14 (13) FADC boards were em-
 493 ployed in the HPS Test Run to read out the top (bottom)
 494 half of the ECal.

495 6. Trigger and Data Acquisition

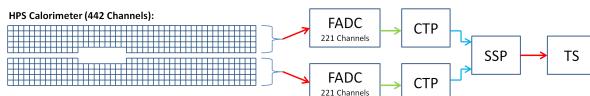

496 The DAQ system handles acquisition of data from the
 497 ECal and SVT sub-detectors with two DAQ architec-
 498 tures. The SVT DAQ is based on Advanced Telecom
 499 Communications Architecture (ATCA) hardware while
 500 the ECal uses VMEbus Switched Serial (VXS) based
 501 hardware. Data from the sub-detectors are only read
 502 out when a trigger signal from the trigger system is re-
 503 ceived.

504 6.1. Trigger system

505 The trigger system is designed to select time coinci-
 506 dences of electromagnetic clusters in the top and bot-
 507 tom halves of the ECal satisfying loose kinematic se-
 508 lections optimized on simulated A' events to further re-
 509 duce the rate. The trigger system need to be essentially
 510 dead time free, handle rates up to 50 kHz and impor-
 511 tantly supply a trigger time relative to the beam bunches

512 with 8 ns to reduce the background from out-of-time
 513 hits in the high occupancy regions of the SVT. Figure 8
 514 shows a schematic overview of each stage of the system.
 515 Each channel on the FADC board has an independent data path to send 5-bit pulse energy and 3-bit pulse
 516 arrival time information every 32 ns to a trigger processing
 517 board (CTP), which is in the same crate. The
 518 3-bit pulse arrival time allows the trigger to know the
 519 pulse timing at 4 ns resolution. Contrary to the read-
 520 out path described in Sec. 5.3, this energy is a pedestal-
 521 subtracted time-over-threshold sum with programmable
 522 offsets and minimum threshold discriminator for each
 523 channel. With input from all FADC channels, i.e. one
 524 half of the ECal, the CTP performs cluster finding and
 525 calculates cluster energy and timing information. The
 526 3x3 fixed-window, highly parallel, FPGA-based cluster
 527 algorithm simultaneously searches for up to 125 clusters
 528 with energy sum larger than the programmable energy
 529 threshold (\approx 270 MeV). Crystals in the fixed-window
 530 are included in the sum if the leading edge of the pulse
 531 occurred within a 32 ns time window to take into ac-
 532 count clock skew and jitter throughout the system. The
 533 CTP only accepts clusters with the locally highest en-
 534 ergy 3x3 window to deal with overlapping and very
 535 large clusters. The sub-system board (SSP) receives the
 536 clusters from the top and bottom half CTP at a max-
 537 imum of 250MHz and searches for pairs of clusters in
 538 an 8 ns wide coincidence window. The SSP sends trig-
 539 gers to the trigger supervisor (TS), which generates all
 540 the necessary signals and controls the entire DAQ sys-
 541 tem readout through the trigger interface units installed
 542 in every crate that participate in the readout process.
 543

544 The trigger system is free-running and driven by the
 545 250 MHz global clock and has essentially zero dead
 546 time at the occupancies expected for HPS. The trigger
 547 supervisor can apply dead time if necessary, for example
 548 on a ‘busy’ or ‘full’ condition from the front-end elec-
 549 tronics. The system is designed to handle trigger rates

575 SVT half-modules (60 APV25 ASICs) are digitized on 624
576 the Rear-Transition-Module (RTM), a custom board on 625
577 the back side of the ATCA crate, interfacing the HPS- 626
578 specific readout to the generic DAQ components on the 627
579 COB. A pre-amplifier converts the APV25 differential 628
580 current output to a different voltage output scaled to the 629
581 sensitive range of a 14-bit ADC operating at the system 630
582 clock of 41.667 MHz. The RTM is organized into four 631
583 sections with each section supporting three SVT half- 632
584 module hybrids (15 APV25 ASICs). The RTM also 633
585 includes a 4-channel fiber-optic module and supporting 634
586 logic which is used to interface to the JLab trigger 635
587 system supervisor. Each section of the RTM is input to a 636
588 DPM which apply thresholds for data reduction and 637
589 organizes the sample data into UDP datagrams. The DPM 638
590 also hosts an I²C controller used to configure and mon- 639
591 itor the APV25 ASICs. A single ATCA crate with two 640
592 COB cards was used, one supporting four DPMs and 641
593 one supporting three DPMs and one DPM that is con-
594 figured as the trigger and data transmission module. The
595 two COB cards and their DPMs are interconnected with
596 a 10 Gb/s switch card [21] which also hosts two 1Gb/s
597 Ethernet interfaces to the external SVT DAQ PC.

598 The external PC supports three network interfaces:
599 two standard 1 Gb/s Ethernet and one custom low-
600 latency data reception card. The first is used for slow
601 control and monitoring of the 8 DPM modules and the
602 second serves as the interface to the JLAB data acquisi-
603 tion system. The third custom low-latency network in-
604 terface is used to receive data from the ATCA crate and
605 supports a low latency, reliable TTL trigger acknowl-
606 edge interface to the trigger DPM. This PC hosts the
607 SVT control and monitoring software as well as the
608 Read Out Controller application used to interface with
609 the JLab DAQ.

610 In order to minimize cable length for the analog
611 APV25 output signal the ATCA crate was located ap-
612 proximately 1 m from the beam line, next to our ca-
613 ble vacuum feed-throughs. Before shielding with lead-
614 blankets was arranged, we observed two failures of
615 normally reliable ATCA crate power supplies, time-
616 correlated to beam instabilities.

617 Although trigger rates during the HPS Test Run were
618 significantly lower, this system was tested at trigger
619 rates up to 20 kHz and 50 MB/s. With optimized event
620 blocking and improved ethernet bandwidth, together
621 with utilizing the overlapping readout and trigger func-
622 tionality of the APV25, the system is capable of being
623 read out at 50 kHz trigger rate.

6.3. General Data Acquisition and Online Computing

Every crate participating in the readout process contains a Readout Controller (ROC) that collects digitized information, processes it, and sends it on to the event builder. For the ECal, both VXS crates run ROC applications in a single blade Intel-based CPU module running CentOS Linux OS. For the SVT DAQ, the ROC application runs on the external PC under RHEL. The event builder assembles information from the ROCs into a single event which is passed to the event recorder that writes it to a RAID5-based data storage system capable of handling up to 100 MB/s. The event builder and other critical components run on multicore Intel-based multi-CPU servers. The DAQ network system is a network router providing 10 Gb/s high-speed connection to the JLab computing facility for long-term storage. For the HPS Test Run, both the SVT and ECal ROC had a 1 Gb/s link to the network router.

7. Reconstruction and Performance

While dedicated electron beam was precluded for the HPS Test Run the short dedicated photon beam run allowed the study of some of the key performance parameters for HPS and also explore the expected trigger rates during electron beam running. This section documents the performance and discusses the results implication for HPS.

7.1. SVT Performance

For the duration of the HPS Test Run all SVT modules and APV25 chips were configured to their nominal operating points [22] with all sensors reverse-biased at 180 V. The sensors were operated within a temperature range of 20 – 24°C. Approximately 97% of the 12,780 SVT channels were found to be operating normally; the fraction of dead or noisy channels varied from 2.4% to 4.7% throughout the HPS Test Run. Most of these losses were due to 2-4 misconfigured APV25 ASICs, a known noisy half-module and problems in two particular APV25 ASICs.

7.1.1. Cluster and Hit Reconstruction

Track reconstruction in the SVT puts stringent requirement on the clustering and hit reconstruction. The multiple scattering in the tracking material dominates the uncertainty in the track parameter estimation and effectively determines the roughly 50 μm (200 μm) requirement on the spatial hit resolution in the non-bend (bend) plane. The high occupancy due to multiple scattered beam electrons in the target close to the beam requires a hit time resolution of 2 ns to efficiently reject

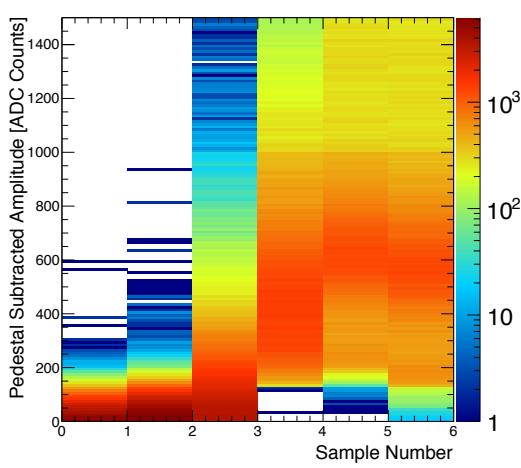

Figure 11: Accumulation of six pedestal-subtracted samples from individual SVT channels associated with hits on tracks.

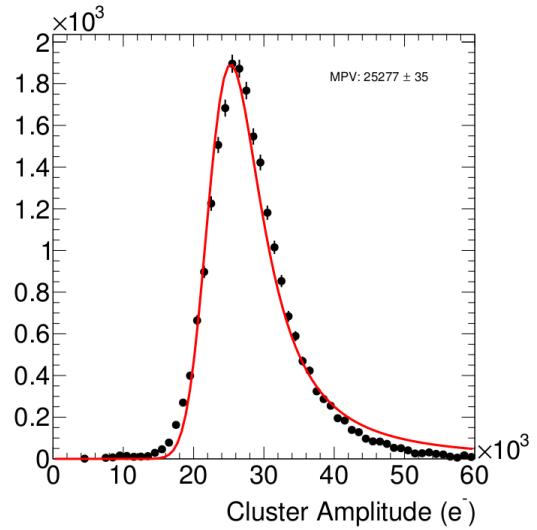

Figure 12: The cluster charge distribution for hits associated with a track follow the characteristic Landau shape.

672 out-of-time hits in HPS. Both the hit time, based on a
 673 fit to the APV25 ASIC pulse shape, and the spatial position
 674 reconstruction rely on having S/N around 25 for
 675 the sensors used in HPS.

676 After a trigger is received, the amplitude of every
 677 APV25 analogue output is sampled and digitized in six
 678 consecutive time bins, separated by roughly 25 ns. A
 679 data reduction algorithm is applied requiring three out
 680 of six samples to be above two times the noise level and
 681 that the third sample is larger than the second or that
 682 the fourth sample is larger than the third. The typical,
 683 pedestal subtracted, pulse shape obtained is shown in
 684 Figure 11. As the figure demonstrates, the SVT was
 685 well timed-in to the trigger with the rise of the pulse
 686 at the 3rd sampling point. In order to find the time, t_0 ,
 687 and amplitude of each hit, the six samples from each
 688 channel are fitted to an ideal $CR - RC$ function. Note
 689 that in the HPS Test Run the APV25 ASICs were oper-
 690 ating with a 50 ns shaping time. These hits are passed
 691 through a simple clustering algorithm which forms clus-
 692 ters by grouping adjacent strips with the position of
 693 a cluster on the sensor determined by the amplitude-
 694 weighted mean. With a linear gain up to ≈ 3 MIPs,
 695 the cluster charge for hits associated with a track fol-
 696 low the characteristic Landau shape, see Figure 12. A
 697 noise level between $1.1 - 1.5 \times 10^3$ electrons was estab-
 698 lished through multiple calibration runs giving a signal
 699 to noise ratio of $21 - 25$, in line with the requirement for
 700 HPS. Radioactive source tests were used to provide the
 701 absolute charge normalization. After clustering hits on

702 a sensor, the hit time for each cluster is computed as the
 703 amplitude-weighted average of the individually fitted t_0
 704 on each channel. The t_0 resolution is studied by com-
 705 paring the cluster hit time with the average of all cluster
 706 hit times on the track shown in Figure 13. After cor-
 707 recting for offsets from each sensor (time-of-flight and
 708 clock phase) and accounting for the correlation between
 709 the t_0 and track time, the extracted t_0 resolution is 2.6 ns.
 710 This is somewhat worse than the approximately 2 ns res-
 711 olution expected for S/N=25 which we attribute to the
 712 true pulse shape differing from our idealized fit function
 713 which will be improved in the future [23]. Reducing the
 714 APV25 ASIC pulse shaping time to 35 ns will also im-
 715 prove time resolution. These results show that we can
 716 operate with the six sample readout mode of the APV25
 717 chip and achieve time resolution adequate for pileup re-
 718 jection during electron running in HPS.

719 Good agreement was obtained between observed and
 720 simulated occupancies after taking into account dead or
 721 noisy channels. The hit reconstruction efficiency was
 722 estimated by measuring the number of good tracks with
 723 a hit close to the extrapolated intersection of a given
 724 sensor that was excluded from the track fit itself. Tracks
 725 which intersect regions with known bad channels or
 726 pass very close to the edge region were excluded. The
 727 hit reconstruction efficiency, see Figure 14, was mea-
 728 sured to be above 98% and fairly uniform across the
 729 SVT.

730 The spatial resolution of similar microstrip sensors is

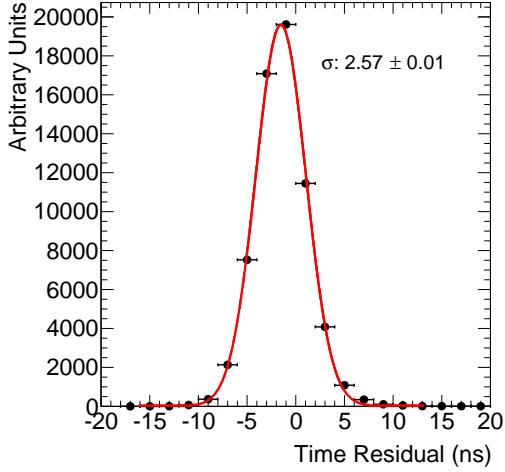

Figure 13: The residual of individual cluster times with the average of all clusters on the track.

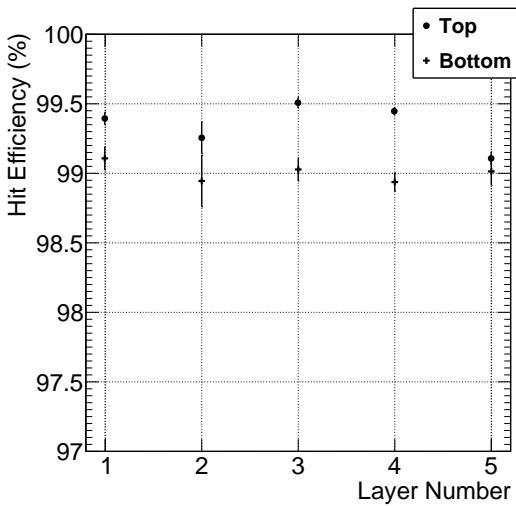

Figure 14: The hit reconstruction efficiency as a function of detector layer.

well established by test beam data, against which the charge deposition model in the simulation is validated. This resolution can be parameterized as a function of the total signal to single-strip noise and the crossing angle of tracks through the sensor. The single-hit resolution for charged particles with signal-to-noise ratio above 20, as demonstrated here, is relatively constant at approximately $6 \mu\text{m}$ for tracks that enter approximately normal to the sensors as in HPS. This resolution is significantly better than the requirement for reaching the mass and vertex resolutions required for HPS.

7.1.2. Momentum and Vertexing Resolution

Good track reconstruction performance is crucial to HPS. Simulations show that track momentum resolution of 4-5% is needed to reach the expected A' mass resolution. The precise reconstruction of the production vertex to reject prompt QED background requires impact parameter resolutions between $100\text{-}250 \mu\text{m}$ for tracks between $0.5\text{-}1.7 \text{ GeV}/c$. These key performance parameters were studied in the HPS Test Run by selecting e^+e^- pairs from photon conversions. Pairs of oppositely charged tracks, one in the top and one in the bottom half of the SVT, with momentum larger than $400 \text{ MeV}/c$ were selected and basic distributions of pair production kinematics were studied. The kinematics are relatively well reproduced as shown in Figure 15.

The expected momentum resolution from simulation is between 4-5% for tracks in the momentum range of the HPS Test Run. By comparing, between data and simulation, the shapes of the kinematic distributions for single- and two-track events, we estimate an agreement with the nominal scale and resolution to within 10%.

In the HPS Test Run, as well as in electron running with HPS, the dominant source of uncertainty in the tracking and vertexing is multiple Coulomb scattering. For the vertexing performance the foremost difference compared to electron beam running is that the target was located approximately 67 cm upstream from our nominal target position; giving almost collinear tracks in the detector. The increased lever arm over which tracks are extrapolated widens the resolution with up to a factor of eight (depending on momentum) compared to what is achieved at the nominal electron target position for HPS. Figure 16 shows the horizontal and vertical positions of the extrapolated track at the converter position. While residual alignments show small shifts, the good agreement between data and simulated events of the widths indicates a good understanding of the material budget and distribution in the SVT. Having the

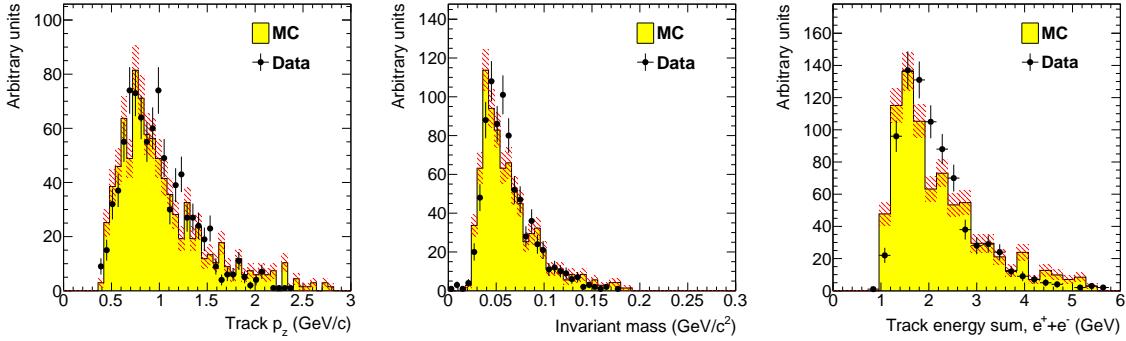

Figure 15: Kinematic distributions for e^+e^- pairs selected by opposite charged tracks in the top and bottom half of the tracker: track momentum in the top half of the SVT (left), invariant mass (middle) and the sum of the track energy for the pair (right).

dominant contribution to the vertex resolution approximately right demonstrates that the Gaussian part of the vertex resolution in HPS, with a target at 10 cm, will be calculated.

7.2. ECal Performance

During the HPS Test Run 385 out of 442 modules (87%) were used in offline reconstruction, 39 modules were disabled or not read out (no FADC channel available, no APD bias voltage or masked out due to excessive noise) and 18 were masked offline due to noise.

The integrated pulse of each FADC channel was converted to energy by subtracting a pedestal and applying a conversion factor to convert ADC counts to energy. The pedestals are measured using special runs where each trigger records 100 samples of signals from the APDs with 4 ns between each sample. The pedestals were extracted from the part of the window before the actual hit in the calorimeter. Modules with signal above the threshold are clustered using a simple algorithm similar to the one deployed for the trigger (see Sec. 6.1). Due to the high effective crystal readout threshold of 73 MeV the average number of crystals in a cluster was ~ 3 and the simple clustering algorithm worked well for reconstruction of the detected shower energy. An average noise level of approximately 15 MeV per crystal was measured in special pedestal runs.

The ratio of the ECal cluster energy E to the momentum p of a matched track in the SVT was used to determine the conversion factors from ADC counts to energy. To compare data and simulation, all inoperable or noisy channels in the SVT and ECal were disabled in both data and simulation so that any efficiency or bias that affect the data should be reflected in the simulation. Iteratively, conversion coefficients for each crystal were adjusted until the E/p ratio in data and simulation were

similar. The distribution of the E/p ratio in data and simulation are compared in Figure 17. The peak position of the distribution indicates the sampling fraction of the ECal, the fraction of the incident particle energy measured in the cluster. The width and tails of the distribution in data indicates imperfect calibration and noise of the ECal modules. This level of calibration and the agreement with simulation was found to be sufficient to study normalized event rates in the HPS Test Run.

Since the A' trigger in HPS is relatively insensitive to the energy resolution this level of performance would be adequate. However, improvements are needed to achieve the expected energy resolution in HPS ($< 4.5\%/\sqrt{E}$). The noise and thresholds need to be closer to 10 MeV the thresholds will be lowered and a more elaborate calibration technique needs to be employed. In addition the number of working channels needs to be improved by equipping the detector new and complete electronics for each channel.

7.3. Trigger Performance

As described above in Sec. 6, the energy from each crystal is measured differently in the trigger and what is readout from the ECal. The trigger performance was studied by simulating the trigger for each event and comparing to how the events were actually triggered. To eliminate trigger bias, we use a tag and probe method: to study the trigger performance in one half of the ECal, we select events which triggered the other half and where there was exactly one probe cluster in the ECal half under study. We then measure trigger efficiency as the fraction of tagged events that fired the trigger in the probe half as a function of the probe cluster energy, shown in Figure 18. The trigger turn-on is slow and reaches an uneven plateau at about 700 MeV

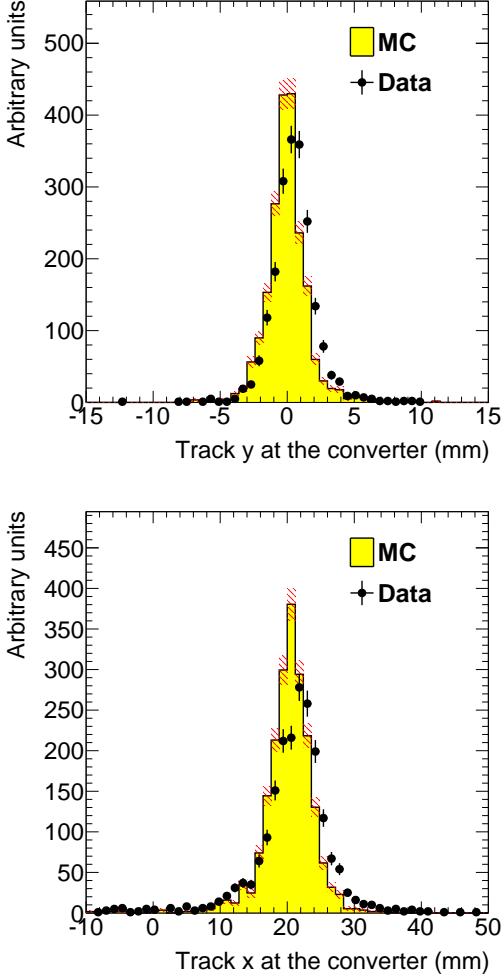

Figure 16: Vertical (top) and horizontal (bottom) extrapolated track position at the converter position taking into account the measured fringe field.

Figure 17: The ECal energy over track momentum ratio (E/p) comparing data and simulation for single cluster triggers in the top half of the ECal.

for two reasons; gain variations between different crystals lead to the threshold variations and the nonlinearity of the time-over-threshold integral means that the effective threshold is higher for clusters that span multiple crystals. The effective trigger threshold is therefore dependent on position and energy of the particle as well as cluster multiplicity.

As a cross-check we simulate the FADC trigger path by converting from readout hits (with fixed-size window integration) to trigger hits (time-over-threshold integration). The CTP clustering algorithm and the trigger decision from the SSP are simulated before we compare the trigger decision and trigger time to what was reported by the actual trigger. For every event, the trigger reports the trigger decision as a bit mask (top half, bottom half or both) and the time the trigger fired. The turn-on from the trigger threshold was measured to be 1280 in units of ADC counts as expected. The threshold was not perfectly sharp because of uncertainties in the conversion from readout to trigger hits described above, but based on comparisons with simulation we found that the trigger worked exactly as specified.

7.4. Trigger Rate Comparisons

Trigger rates observed in the HPS Test Run are dominated by multiple Coulomb scattered e^+e^- pairs in the converter. In simulated events, the rate of triggers depend on the modeling of the pairs' angular distribution and the subsequent multiple Coulomb scattering in the converter. Rates from different converter thicknesses

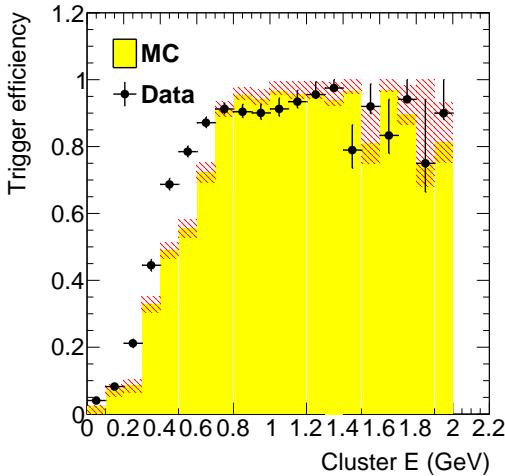

Figure 18: Trigger efficiency in both halves of the ECal for data and simulation as a function of cluster energy.

Converter (% X_0)	1.60	0.45	0.18
EGS5	1162 ± 112	255 ± 28	94 ± 17
Geant4	2633 ± 250	371 ± 38	114 ± 18
Observed	1064 ± 2	196 ± 1	92 ± 1

Table 4: Observed and predicted event rate (in Hz) normalized to 90 nA for three different converter thicknesses. The uncertainty on the prediction includes systematic uncertainties from ECal alignment, background normalization, beam current normalization and limited statistics in the simulation.

are used to study the varying multiple Coulomb scattering contribution (pair production angular distribution is constant), and are compared with Geant4 [24] standard multiple scattering model and EGS5 [25]. Restricting clusters to a well calibrated region of the ECal and subtracting the “no converter” background we see agreement with the rates predicted by the EGS5 simulation program, see Table 4. This gives further confidence that the dominant source of background occupancy for HPS, multiple Coulomb scattered beam electrons, is well described.

8. Summary and Outlook

The HPS Test Run experiment, using a simplified version of the apparatus planned for the full HPS experiment in a parasitic photon beam, demonstrated the feasibility of the detector technologies proposed for the silicon vertex tracker, electromagnetic calorimeter, and data acquisition systems. Performance from each of these subsystems has been shown to be adequate

to conduct the full experiment successfully with some identified improvements. Studies of multiple Coulomb scattering tails of electrons and positrons from photon conversions further backs expectations from simulation, giving credence to estimates of the detector backgrounds expected in electron beam running for HPS.

9. Acknowledgements

The authors are grateful for the support from Hall B at JLab and especially the Hall B engineering group for support during installation and decommissioning. They also would like to commend the CEBAF personnel for good beam performance, especially the last few hours of operating CEBAF6. The tremendous support from home institutions and supporting staff also needs praise from the authors.

This work has been supported by the US Department of Energy, the National Science Foundation, French Centre National de la Recherche Scientifique and Italian Istituto Nazionale di Fisica Nucleare. Rouven Essig is supported in part by the Department of Energy Early Career research program DESC0008061 and by a Sloan Foundation Research Fellowship. Authored by Jefferson Science Associates, LLC under U.S. DOE Contract No. DE-AC05-06OR23177.
